ABSTRACT

Objective: Cholecystectomy, mostly due to cholelithiasis, is one of the most common surgical procedures utilizing a significant amount of healthcare resources. As there are a huge number of cases, for example approximately 360 cases per year in our region, outlining this commonly encountered lesion should be recorded. Also, in an attempt to delineate the outline of the pattern, age and sex distribution of cholecystitis in the whole Kingdom, a comparative analysis is also included in this study with 7 other studies published from different parts of the Kingdom.

Methods: Our study consisted of 740 consecutive laparoscopic cholecystectomies mostly for cholelithiasis received in a time frame of 3.5 years (for example between January 1997 through to May 2000) by the Department of Histopathology retrieved from the records of the laboratory. The outline of main gallbladder pathologies was tabulated. The number of gallbladders received with stones was also calculated. Age and sex distribution for gallbladder pathology and gallstones was also tabulated.

Results: There were 131 males (18%) and 609 (82%) females, with a female ratio male 4:6:1. Benign lesions comprised 99% (mean age 36), mostly chronic cholecystitis (97%) and acute cholecystitis which constituted 15 cases only (2%), malignant lesions comprised only 7 cases for example 1% of all lesions (mean age 65).

Conclusion: Cholecystectomy is the most common surgical procedure and as described in literature approximately 600,000 cholecystectomies are performed each year in the United States of America (USA), and gallstone related disease accounts for an estimated overall cost of more than 5 billion dollars annually in USA. This shows the importance of this organ and requires the pathologist to be familiar with the normal anatomy, histologic characteristics and pathologic states of this organ. While the advent of laparoscopic cholecystectomy has revolutionized the manner in which routine gallbladder surgery is performed, it has not altered the type of specimen that the pathologist receives for processing. With a few exceptions, the diagnosis of disorders of the gallbladder is quite straightforward, as most diseases are associated with cholelithiasis. When they are encountered at the time of frozen section, they often present with a great diagnostic challenge, even for pathologists with extensive experience. The mean rate of cholecystectomy with respect to total number of operations was 5%, which is not as high as reported by other studies from the Kingdom of Saudi Arabia approaching 15%. The exact prevalence of gallbladder pathologies and gallstones is still unknown for the Kingdom of Saudi Arabia. The majority of the studies from the Kingdom of Saudi Arabia have entertained the surgical techniques and interventions especially the laparoscopic procedures.

Keywords: Gallbladder lesions, gallbladder malignancy, chronic cholecystitis, cholesterolosis.

Saudi Med J 2001; Vol. 22 (10): 885-889
Kingdom of Saudi Arabia have suggested that the problem is very common. A very large study from 14 hospitals of the country's Eastern province had reported that the frequency of choledocholithiasis has increased by 98%, a finding not explained by the 57% increase in the population or the 87% increase in other operation rates. This led us to analyze 740 surgical cholecystectomy specimens received in the Department of Surgical Pathology, King Abdul Aziz University Hospital (KAUH), Jeddah, Kingdom of Saudi Arabia during the time frame of 3 years and 4 months (from January 1997 to May 2000).

**Methods.** King Abdul Aziz University Hospital is a 250 (functional) bedded tertiary care hospital located in Jeddah. In an attempt to delineate the spectrum of gallbladder lesions, data on these surgical specimens were collected between January 1997 and May 2000 was retrieved from the records of the laboratory, keeping track of age, sex, histopathological diagnosis and presence of stones. All gallbladder specimens are received in formalin since prompt fixation is required for the mucosa, which is quite susceptible to bile-related autolysis. A total of 3 full-thickness sections (one each from fundus, body, and neck/cholecystic duct region) of the gallbladder are routinely taken and placed in one or 2 cassettes. Pericystic duct lymph node if present is also sampled. If gallstones are not readily apparent, the bile is strained to assess for minute stones or floating cholesterol polyps, and the viscosity of the bile is described in the gross description of the specimen. The detailed characteristic of the stones is also mentioned in the gross description. Most of the times the gallbladder is received open, with stones retrieved by the surgeons. In these cases the description provided by surgeons regarding stones on the request form are followed.

**Results.** We analyzed all the gallbladder specimens over a time period of 40 months, and found a total of 740 specimens. We came across a total of 740 cases. The mean age was 36. There were 609 (82%) females and 131 (18%) males with a female to male ratio of 4.6:1 with seven of the cases (1%) having carcinoma. Gallstones were found in 576 specimens (78%) and their distribution in each.

**Discussion.** It is a common impression that gallstones are remarkably "common" in Saudis; no exact prevalence figures are available. Comparison of the prevalence of gallstones among different populations is notoriously difficult not only with differences in availability of diagnostic facilities and attitudes toward treatment, but many patients who have gallstones remain symptom free. Thus, in Great Britain, only one in 7 individuals with gallstones results in cholecystectomy, whereas in one population-based Italian study, 78% of subjects found to have gallstones were asymptomatic. Three major factors can be implicated in gallstone formation, increased biliary cholesterol, decreased bile acids and nucleation defect(s). Certain subjects attributable risk-factors were thought to modulate these gallstone formation factors. Irreversible risk factors including age and sex, possible reversible factors include obesity, parity, oral contraceptives, family history of gallstones, smoking, diabetes mellitus, plasma lipids, dietary factors and possibly major abdominal surgery. There are a lot of inconsistencies in the literature with regard to these factors. Although we have not specifically concentrated on risk factors of gallstone formation in the present study they are briefly discussed as of their importance in the subject. There is one study reported from Medina,19 in which these risk factors of gallstone formation in young women are discussed separately. In the present study we have concentrated more on gallbladder pathologies and have calculated the rates of stones in each diagnosis. It has been estimated that approximately 20 million people in the USA have gallstones and approximately half of them are asymptomatic. Gallstones are described to be present in almost all the cases of chronic cholecystitis. In our study, gallstones were found in 78% of all specimens. They were found in

*Number of patients with each diagnosis, percentage **Percentage of patients in each diagnosis which had stones.
of female specimens with the peak age in the 3rd decade, and 71% of males with peak age in the 4th decade. This figure might not represent the true picture of prevalence of stones in cholecystectomy specimens as most of the time the stones are handed over by the surgeons to patient relatives as a grant. But we have tried to be as precise as possible by following the descriptions reported by surgeons on laparoscopy request forms. Cholelithiasis has been described as the most prevalent disorder of the biliary system. At least 10% of the adult population of the USA harbor gallstones. In the pediatric age group gallstones are quite uncommon (0.13-0.22%). Stones grow for the first 2 to 3 years, after which their growth stabilizes. In literature, ultrasound surveys have shown a female to male ratio of 2:3 in the younger adult age groups and an increasing female prevalence with age. After age 60, the prevalence of gallstones in men and women is 10% to 15% and 20% to 40%, respectively. Major risk factors include older age (peak, 6th and 7th decades), female sex, multiple pregnancies, obesity or rapid weight loss, hypertriglyceridemia and low high-density lipoprotein (HDL) cholesterol (but not elevated serum cholesterol) and ethnic predisposition. There are 81 specimens with cholelithosus totaling 11%. In literature, cholelithiasis is reported in approximately 20% of cholecystectomy specimens. This is characterized by the accumulation of cholesterol crystals and triglyceride in aggregates of subepithelial macrophages and, to a lesser extent, in the gallbladder epithelium itself. Patients with this condition were mostly women such as 73 cases (12%) with a mean age of 34 years. It has been described that cholesterolosis may clinically improve after cholecystectomy. Although the origin of cholesterolosis is unknown, most theories stress that either supersaturation of the bile with cholesterol, which is found in many but not all cases, or abnormal lipid transport across the mucosa leads to the formation of the lipid deposits. Bile cholesterol supersaturation is also seen with cholesterol gallstones. In our study gallstones were found in only 45% of the specimens. Literature from the west shows that more than 50% of surgically resected gallbladders, but only 10% of autopsy gallbladders with cholelithiasis have gallstones (usually cholesterol type), however, this demonstrates the inconsistent relationship between these 2 conditions. There is no association of cholelithiasis with elevated blood cholesterol. In most cases of cholesterolosis, the gross macroscopic description showed yellow, non-polyloid, punctuate deposits in a diffuse distribution. They look like the surface of a strawberry hence, the term strawberry gallbladder. Metaplastic epithelium in the gallbladder can be divided into 2 major groups, namely, gastric (pyloric gland and surface epithelial) and intestinal, although there is also a rare squamous variety. The changes increase in frequency with age, they are more numerous in the context of gallstones, can be quite focal, and can involve any region of the organ. In our series, metaplastic epithelium was found only in 17 (3%) of cases of which 12 (88%) pyloric and 2 (12%) with intestinal metaplasia. No squamous metaplasia was reported in our series. Reports from the west have shown that pyloric gland (pyloric, antral, or mucous gland) metaplasia is most common and is found in 66%-84% of cholecystectomy specimens. Lobules of metaplastic pyloric glands are usually scattered in the lamina propria, although they may extend through the muscular layer. Small submucosal nodules or polyps may result, often associated with overlying papillary hyperplasia. They have often been reported in the literature as a form of hyperplastic polyp. Intestinal metaplasia represents replacement of the normal epithelium by cells with an intestinal phenotype (goblet cells, endocrine cells, Paneth cells, and absorptive cells, rarely with a distinct brush border) and has been reported in 12% to 52% of gallbladders removed for cholecystitis or chronic cholecystitis. Squamous metaplasia is rare (<0.1%) of cholecystectomy specimens. It may be associated with porcelain gallbladder or squamous dysplasia or be found adjacent to invasive squamous cell carcinoma. So the rate of metaplastic changes were very low in comparison with the rest. This might be explained by the fact that same pathologist do not describe mild metaplastic changes in their reports and also as most metaplastic changes occur focally, a more thorough sampling and careful interpretation of changes is required to get the accurate rates. There were 16 cases of acute cholecystitis and 2 cases of acute suppurative cholecystitis making 11% of total together. All of them were found to be associated with gallstones. These studies were composed of a smaller number of patients, having a lower statistical power. Reports from the west have shown variable rates of acute cholecystitis in cholecystectomy cases, but overall 5%-10% is reported by the majority of reports. There were only 7 cases of gallbladder carcinoma in our study. One of them occurred in a male and was diagnosed as an invasive papillary carcinoma, 6 in females as well, as moderately differentiated adenocarcinoma. The mean age for carcinoma was 65 years. There were 2 cases in females which occurred in the late 3rd decade but the rest of them occurred only in more than 75 age group. Amazingly reports from the west have shown carcinoma of the gallbladder as the most common malignancy of the biliary tract and the 5th most common malignancy of the gastrointestinal tract, with an incidence of 2.5 cases per 100,000 population per year. The incidence has reported to vary considerably worldwide and even within the same country among
different ethnic groups. Higher rates are found in Chile, Mexico, Bolivia, and Japan, while in the USA, Hispanic Americans and southwestern Native Americans are affected more frequently. Gallbladder carcinoma has been reported to be found in 1% to 2% and 0.1% of open and laparoscopic cholecystectomies, and causes 6,500 deaths annually in the USA. It is a disorder primarily of the elderly (mean age, 65 years; 90% are in their 6th decade or older). About 10% of gallbladders removed from patients more than 65 years of age harbor invasive carcinoma. This malignancy occurs more frequently in women (2-3:1), and cholecithiasis is found in 70%-90% of patients. The risk of carcinoma developing in a patient with cholecithiasis is only 1%-3%, but the risk appears to be higher when the stones are larger than 3 cm in diameter. Other associated conditions, which account for a minority of cases of gallbladder carcinoma, include porcelain gallbladder,\textsuperscript{21-23,30-60} minizzi syndrome,\textsuperscript{47} cholelithiasis,\textsuperscript{45,47} ulcerative colitis,\textsuperscript{62} primary sclerosing cholangitis,\textsuperscript{63} familial adenomatous polyposis or Gardner syndrome\textsuperscript{60} and peutz jeghers syndrome.\textsuperscript{64} Since this study has not probed into the etiological and detailed clinical factors, these associations were not analyzed here. There was only one study from the Kingdom of Saudi Arabia, which has reported the rate of gallbladder carcinoma to be only 0.5%. In our study this rate was 0.95%, close to the lower value of range reported from the USA. A comparative analysis was carried out with 7 other studies published in the Kingdom of Saudi Arabia.\textsuperscript{31,12,38-33} Results from all these studies were quite similar.

In conclusion, the rate of gallbladder diseases and stones are high and these reports from other parts of Kingdom of Saudi Arabia are suggesting that the problem is so common that it deserves a large scale population based study to get a more accurate picture.
